Abstract

Objective: To evaluate whether there is any difference between radiographic axial spondyloarthritis (r-axSpA), also termed ankylosing spondylitis (AS), and non-radiographic (nr-) axSpA, with respect to subclinical myocardial dysfunction using speckle tracking echocardiography (STE).

Methods: This was a cross-sectional case control study. We included 72 patients with AS, 38 patients with nr-axSpA, and 56 age-matched healthy subjects. Patients with cardiac disease and cardiac risk factors affecting STE were excluded. The disease burden evaluated by the BASDAI, BASFI, BAS-G, and ASAS-HI scores were comparable in both the r- and nr-axSpA groups. A detailed echocardiographic examination including the M-mode, Doppler, and STE was applied to whole study population.

Results: Duration of the disease, the use of an anti-TNFα agent, and CRP levels were higher in patients with AS. Although the AS, nr-axSpA, and control groups had similar ejection fraction values (59±5.2, 60±4.6, and 60±4.6, respectively, and p=0.499), the global longitudinal peak systolic strain (GLS) (20.5±3.3 vs. 21.1±3.5, and 22.3±2.4, respectively, and p=0.05) was different between the groups. In a post-hoc analysis, GLS was not different between the nr-axSpA and control groups, and it was significantly lower in patients with AS. In the univariate analysis, peripheral arthritis (p=0.035) and age (p=0.032) were correlated with GLS. A multivariate regression analysis demonstrated that peripheral arthritis (p=0.009) was the only independent GLS predictor.

Conclusion: Subclinical myocardial dysfunction as assessed by GLS was present in AS, but not in nr-axSpA patients. Thus, GLS could be used as a differentiating factor between radiographic and nr-axSpA patients.

Keywords: Speckle tracking echocardiography, axial spondyloarthritis, ankylosing spondylitis, echocardiography, myocardial dysfunction

Introduction

Axial spondyloarthritis (axSpA) is a group of chronic inflammatory diseases affecting mainly the axial skeleton, including the sacroiliac joints and spine. There are two subtypes of axSpA: a non-radiographic form (nr-axSpA), which is defined as the absence of definite sacroiliitis on conventional radiographs, and a radiographic form (r-axSpA), which is better known as ankylosing spondylitis (AS). In addition to radiographic manifestations, a higher female predominance and lower serum C-reactive protein (CRP) levels might be other characteristics differentiating patients with nr-axSpA from those with AS. However, clinical disease activity measures and response rates to tumor necrosis factor inhibitors (TNFi) were found to be comparable in both patients axSpA groups (1).

The relationship of chronic inflammation with the development of cardiovascular diseases (CVD), especially atherosclerosis, has been demonstrated. Inflammatory rheumatic diseases may cause an increased frequency of CVD in otherwise traditional risk factors. It has recently been demonstrated that the frequency of major cardiovascular events was similar in chronic inflammatory diseases such as rheumatoid arthritis, psoriatic arthritis, and in patients with axSpA (2). CVD have also been reported to be a prominent cause of mortality in axSpA (3). It has been suggested that a 10-year risk of CVD may be related to both the radiographic grade of sacroiliitis and spinal radiographic damage in axSpA (4). In accordance with these data, a previous study by the current authors showed that myocardial functions were also impaired in axSpA when they assessed using conventional echocardiographic studies (5).
Speckle tracking echocardiography (STE) is a highly sensitive and accurate method for detecting subclinical ventricular dysfunction before the development of clinical myocardial dysfunction as assessed by conventional two-dimensional echocardiography (6). Recent studies using STE have shown that patients with axSpA have subtle left ventricular myocardial dysfunction (7, 8). However, these studies have focused on the whole group of patients with axSpA, and no clear statement can be made about whether there is a difference between AS and nr-axSpA patients regarding to subclinical myocardial dysfunction. Therefore, in this study, we aim to evaluate left ventricular myocardial function using advanced STE in patients with and without radiographic axSpA and to determine the risk factors for myocardial dysfunction in those patients.

Methods

Study population

This study was conducted on patients with axSpA aged >18 years, who were followed up in a rheumatology clinic between July 2017 and March 2018. A total of 72 consecutive patients with AS and 38 patients with nr-axSpA according to the Assessment of Spondyloarthritis International Society (ASAS) criteria for axial spondyloarthritis (9) were included in the study. A control group was formed of 56 age- and gender-matched healthy subjects. Patients with hypertension, diabetes mellitus, known cardiac diseases (e.g., coronary artery disease, acute and chronic heart failure, cardiac pacemaker, moderate and severe valve disease, atrial fibrillation) and those who had a history of stroke or transient ischemic attack, renal failure, liver disease, and poor echogenicity that could affect STE were excluded from the analysis.

A written informed consent form was obtained from all subjects. This study was reviewed and approved by the Institutional Review Board (Decision number: 299/2017)

Clinical, laboratory, and radiologic evaluation

All patients underwent a detailed evaluation. Patients’ socioeconomic and demographic characteristics, including age, gender, cigarette consumption, age at the onset of symptoms, and age at diagnosis, were obtained using a standard questionnaire. At the time of evaluation, all patients completed the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) (10, 11), Bath Ankylosing Spondylitis Functional Index (BASFI) (12), Ankylosing Spondylitis Quality of Life (ASQoL) (13), Assessment of Spondylarthropathies International Society—Health Index (ASAS-HI) (14), the Bath Ankylosing Spondylitis Patient Global Score (BAS-G) (15), and a health assessment questionnaire (HAQ). The ankylosing spondylitis disease activity score (ASDAS)-CRP (16) was also calculated and obtained. The HLA-B27 status was obtained from the patient’s medical records, if available. Laboratory parameters including a complete blood count, sedimentation rate, CRP, and lipid profile were also obtained. Radiographic images of the pelvis and the lumbar and cervical spine were assessed by a single experienced rheumatologist. The radiographic images were evaluated according to the modified Stoke AS Spine Score (mSASSS) (17) and prior intra-observer intra-class coefficient and inter-observer ICC values for mSASSS scoring were estimated as 0.932 and 0.933-0.948, respectively, for the reader. All radiographs were also evaluated regarding whether there was a hip involvement and syndesmophyte by the same reader. Kappa (κ) value for the existence of syndesmophyte was estimated as 0.467 (%95 CI; 0.401-0.559).

Echocardiographic examination

All subjects underwent a detailed evaluation with two-dimensional transthoracic echocardiography, including M-mode color Doppler, tissue Doppler, and strain imaging studies. A commercially available ultrasound machine EPIQ 7C (Philips Medical Imaging, Eindhoven, the Netherlands) was used in all echocardiographic examinations. Standard two-dimensional and Doppler echocardiographic examinations were performed based on the American Society of Echocardiography/European Association of Echocardiography guidelines (18, 19). Two independent and experienced echocardiographers, blinded to the patients’ clinical data such as diagnosis, symptoms, and treatment of axial spondyloarthritis, performed and examined the echocardiographic recordings. Left ventricular ejection fraction (LVEF) was obtained. The GLS value for the existence of syste-

Statistical analysis

Statistical analysis was performed using the IBM Statistical Package for Social Sciences, Statistics for Windows, Version 21.0. (IBM Corp.; Armonk,
NY, USA. Released 2012). The normality distribution patterns of variables were evaluated using histograms, probability plots, and analytical methods (Kolmogorov-Smirnov). Unless otherwise stated, normally distributed variables and not normally distributed variables were shown as mean±standard deviation and median (interquartile range), respectively. Categorical variables were presented as percentages. The AS and nr-axSpA groups were compared using the independent Student’s t-test and the Mann-Whitney U test, according to normality analyses for continuous variables. Continuous data was compared between the AS, nr-axSpA, and control groups using the one-way analysis of variance, and Tukey’s HSD was used in post-hoc comparisons. Categorical variables were compared using the chi-squared test. Spearman’s rank correlation test was used for bivariate correlations between variables and GLS. Significantly correlated variables were tested in a multivariate linear regression analysis to determine the independent risk factors for strain values. All tests were two-tailed, and the p-value <0.05 was accepted as statistically significant.

Results
Patients’ baseline clinical characteristics are presented in Table 1. The BASDAI, BAS-G, HAQ-S, BASFI, and ASAS-HI scores were found to be similar in patient groups. The mSASSS, duration of disease, and use of an anti-TNFα agent were higher in patients with AS. In addition, serum CRP levels were higher in the AS group, and other laboratory parameters were similar in the groups.

Echocardiographic parameters
The echocardiographic parameters of patients with axSpA and control groups are presented in Table 2. There was no difference between the three groups in respect of left ventricular dimensions, volume, and ejection fraction (p>0.05). With the exception of deceleration time, the parameters representing diastolic functions including the left atrial volume, E velocity, and E/e’ ratio were comparable between the groups.

Although GCS was similar (p=0.839), GLS was different between the groups (p=0.004). Post-hoc tests demonstrated that GLS was comparable in the nr-axSpA and control groups. However, it was significantly lower in patients with AS. The GLS distribution per group is presented in Figure 2. Of the study population, 76% AS and 24% nr-axSpA patients had lower GLS values than the normal reference values (Figure 3).
In a univariate analysis, GLS was correlated with an increasing age (p=0.032) and the presence of peripheral joint involvement (p=0.035). In the multivariate regression analysis, peripheral joint involvement was shown to be the only independent predictor of GLS (p=0.009) (Table 4).
STE, determining the relative length change in a certain part of the myocardium between end-diastole and end-systole, can demonstrate subtle changes in myocardial systolic function. It is less operator dependent and more sensitive than conventional TTE in the demonstration of subtle myocardial dysfunction without clinical signs and symptoms. However, STE is vendor dependent, and there is no clear determination of normal GLS reference values. Current guidelines arbitrarily accept 20% as a normal GLS range (18). There are few studies that have investigated the myocardial function using STE in patients with axSpA. Ustun et al. (8) demonstrated reduced myocardial systolic function in patients with AS, even without CVD as assessed by STE. However, that study did not include patients with nr-axSpA. Chen et al. (7) also showed that patients with axSpA had subtle systolic left ventricular dysfunction using advanced 2-STE analysis, even with an apparently normal LVEF assessed by conventional echocardiography. However, the majority (78%) of patients with axSpA comprised AS patients. In our study, despite mean GLS values of patients with AS within normal limits, majority of the AS patients had lower GLS values than the accepted normal GLS value (18). The current study findings were comparable to those of previous studies. Similarly, AS itself may reduce myocardial functions using STE despite a normal EF, even without cardiovascular risk factors. The results of this study further demonstrated that myocardial functions, using advanced STE and conventional echocardiography, were comparable between patients with nr-axSpA and the healthy population. An additional important finding was that peripheral arthritis was determined as an independent predictor of reduced GLS. Although it is not exactly known how peripheral arthritis is related to impaired myocardial systolic function, CVD occurrence is more frequent in those patients with long-term AS and with peripheral arthritis (25). Patients with AS and peripheral arthritis tend to have a higher inflammatory activity than those without peripheral arthritis, which may contribute to myocardial dysfunction (26, 27).

The main limitations of the present study are that it had the single-center, cross-sectional design and a relatively small number of patients. There is a need for multicenter studies with a larger sample size to be able to reach a more solid conclusion about whether GLS can be used as a differentiating factor between AS and nr-axSpA.

This study indicated that even in the absence of CVD and cardiovascular risk factors, GLS was reduced in patients with AS but was unchanged in patients with nr-axSpA. In addition to conventional echocardiographic methods, STE may add valuable information regarding myocardial dysfunction in axSpA. Therefore, reduced GLS may be used as another distinctive factor between radiographic and nr-axSpA patients.
